### **Calculus for AP Physics-C**

As you will quickly see, Calculus is not really a subject of AP Physics, it is a tool that we use from the first day. However, many of you are now just starting Calculus and a few of you are not taking and have not taken Calculus. For that reason, we have this high speed mini-course to get you able to use the Calculus tools. The material does involve some proofs (only partially done – we will leave the details to your math teachers) but we do cover both parts of Calculus.

To let the cat out of the bag, you all have already done Calculus in first year Physics – multiple times – without knowing it. Every time you used a Tangent Line to find a slope you were doing Differential Calculus. Every time you found an area under a curve you were doing Integral Calculus. The only differences were that we usually used real data points and approximation whereas in Physics (and Calculus) we use equations fitted to real data to find the slopes (Differential Calculus) or the areas (Integral Calculus).

# **Differential Calculus:**

Since we are finding Tangent line slopes without looking at real data, we need to find a way to sneak to sneak up on the slopes. Tangent lines to a curve touch the curve "locally" at only one point (the point of tangency). Since we need two points to compute a slope we will use the Secant Line slope method of finding approximate slopes and then driving the secant line to a tangent line by moving one end of the secant line toward the other end.

Suppose we have the following graph:

Using basic algebra, the slope of the line through the two points (x, f(x)) and  $(x+\Delta x, f(x+\Delta x)) =$  slope of the secant line which is (recalling that slope is rise over run)

Slope = 
$$\frac{f(x + \Delta x) - f(x)}{(x + \Delta x) - x} = \frac{f(x + \Delta x) - f(x)}{\Delta x}$$

Now what we really want is the slope as  $\Delta x$  approaches zero (moving the right hand point closer and closer to the left hand point) and the secant line starts to look like the tangent line touching the function f(x) at only one point "near" x.

Suppose  $f(x) = kx^2$ , what is the slope of the curve at any point (x,f(x))?

Well, lets use equation #1 to find the slope of a particular tangent line.

Slope of 
$$[f(x) = kx^2] = \frac{f(x + \Delta x) - f(x)}{\Delta x} = \frac{k(x + \Delta x)^2 - kx^2}{\Delta x}$$
 (1)

As those of you taking (or already completed) know, A large chunk of Calculus involves sneaky algebraic manipulations which often start out making things messy and then proceed to reduce to something easy.

There are THREE MAJOR TRICKS IN MATHEMATICS that one can do to an expression that does not change the numeric value of the expression:

- 1. Expand any expression that can be expanded.
- 2. Add ZERO to the expression
- 3. Multiply the entire expression by ONE.

We will now use method 1 (also called, MAKE IT WORSE AND SEE WHAT HAPPENS.")

$$\frac{f(x+\Delta x) - f(x)}{\Delta x} = \frac{k(x+\Delta x)^2 - kx^2}{\Delta x} = \frac{k(x^2+2x\Delta x + \Delta x^2) - kx^2}{\Delta x} = \frac{kx^2 + 2kx\Delta x + k\Delta x^2 - kx^2}{\Delta x}$$
$$= \frac{kx^2 + 2kx\Delta x + k\Delta x^2 - kx^2}{\Delta x} = \frac{2kx\Delta x + k\Delta x^2}{\Delta x} = 2kx + k\Delta x$$

Thus the slope of the secant line is  $2kx+k\Delta x$ . Now as  $\Delta x$  approaches zero the slope becomes

Slope of 
$$kx^2 = 2kx$$
 (2)

Suppose we have  $f(x) = kx^3$ , what is the slope? Doing the same thing we have:

$$\frac{f(x+\Delta x) - f(x)}{\Delta x} = \frac{k(x+\Delta x)^3 - kx^3}{\Delta x} = \frac{k(x^3 + 3x^2\Delta x + 3x\Delta x^2 + \Delta x^3) - kx^3}{\Delta x} = \frac{kx^3 + 3kx^2\Delta x + 3kx\Delta x^2 + \Delta x^3 - kx^3}{\Delta x}$$
$$= \frac{3kx^2\Delta x + 3kx\Delta x^2 + \Delta x^3}{\Delta x} = 3kx^2 + 3kx\Delta x + \Delta x^2$$

Thus the slope of the secant line is  $3k^2+3kx\Delta x+\Delta x^2$ . Now as  $\Delta x$  approaches zero both the second and third terms get closer and closer to zero and the slope of the tangent line becomes

Slope of  $kx^3 = 3kx^2$ . (3)

Now getting really fancy, what is the slope of  $f(x) = kx^n$ ?

Well, first we have to remember how to expand an item like  $(a+b)^n$ .

$$(a+b)^{0} = 1$$

$$(a+b)^{1} = 1a + 1b$$

$$(a+b)^{2} = 1a^{2} + 2ab + 1b^{2} = 1a^{2} + 2ab + (terms with b^{2} \text{ or larger terms})$$

$$(a+b)^{3} = 1a^{3} + 3a^{2}b + 3ab^{2} + 1b^{3} = 1a^{3} + 3a^{2}b + (terms with b^{2} \text{ or larger terms})$$

$$(a+b)^{4} = 1a^{4} + 4a^{3}b + 6a^{2}b^{2} + 4ab^{3} + 1b^{4} = 1a^{4} + 4a^{3}b + (terms with b^{2} \text{ or larger terms})$$

$$(a+b)^{5} = 1a^{5} + 5a^{4}b + 10a^{3}b^{2} + 10a^{2}b^{3} + 5ab^{4} + b^{5} = 1a^{5} + 5a^{4}b + (terms with b^{2} \text{ or larger terms})$$
Notice that the first term is always 1a <sup>original power</sup>
and the second term is always (original power)a<sup>original power-1</sup>b
and the rest of the terms have b<sup>(power>1)</sup>
Now, what is  $(x+\Delta x)^{n}$ ?
$$(x + \Delta x)^{n} = x^{n} + nx^{n-1}\Delta x + (bunch of terms)\Delta x^{power} \quad where power \ge 2$$
Now, lets use this idea to find the slope of  $f(x) = kx^{n}$ 

$$\frac{f(x + \Delta x) - f(x)}{\Delta x} = \frac{k(x + \Delta x)^{n} - kx^{n}}{\Delta x} = \frac{k(x^{n} + nx^{n-1}\Delta x + (bunch of terms)\Delta x^{power^{2}}) - kx^{n}}{\Delta x}$$

$$=\frac{kx^{n} + nkx^{n-1}\Delta x + k(bunch of term)\Delta x^{power=2} - kx^{n}}{\Delta x}$$
$$=\frac{nkx^{n-1}\Delta x + k(bunch of term)\Delta x^{power=2}}{\Delta x} = nkx^{n-1} + k(bunch of term)\Delta x^{power=1}$$

But in the last power the phrase "power-1" is still ONE or bigger since the original power  $\ge 2$ ...

The slope of 
$$f(x) = kx^n = nkx^{n-1}$$
 since  $k(bunch \ of \ term)\Delta x^{power-1} \to 0$  as  $\Delta x \to 0$  (4)

What this means is that for any simple power function, the slope is simply the original function times the original power and then the power is dropped by ONE.

#### THIS IS EASY !!

#### An example from Physics:

Suppose you are moving so that your position is given by  $x = 3t^4$ , then your speed (velocity) which is the slope of the position curve must be

 $v = 4(3)t^3 = 12t^3$ .

Now your acceleration (which is the slope of the velocity) must be

$$a=3(12)t^2=36t^2$$
.

If you wish, you can even find the jerk (change in acceleration = slope of acceleration curve) which is

$$j = 2(36)t^1 = 72t.$$

You can even find the snap (change in jerk = slope of jerk curve) which is

$$s = 1(72)t^0 = 72.$$

Going beserk one can find the crackle (snap-crackle-pop = I made it up) which is

$$c = 0(72)t^{-1} = 0$$

Notice that last step. This rule works for ANY power function with any power (positive, negative or decimal).

#### **Basic Examples:**

$$y = f(x) = 2.4x^{4.5}$$
  
Slope = 4.5(2.4) $x^{3.5} = 10.8x^{3.5}$   
 $y = f(x) = -4.2x^{0.5}$ 

Slope = 
$$(0.5)(-4.2)x^{-0.5} = -2.1 x^{-0.5}$$

 $y = f(x) = 11.34x^{-3.4}$ 

Slope = 
$$(-3.4)(11.34)x^{-4.4} = -38.556x^{-4.4}$$

This means that the graphical physics we have done all last year can now be done very easily with a simple formula.

However (there is always a however, isn't there??), not all functions are simply  $f(x) = kx^n$ .

#### Sum Rule:

Suppose we have a function which is the sum of two functions?

y = f(x) = g(x) + h(x) is the standard way of saying the sum of two functions.

An example might be,  $f(x) = 3x^2 + 4x^3$ .

We now have to ask what y = f(x) = g(x) + h(x) really means. Well what does y=f(x) mean? A true mathematician will say it is a set of numeric pairs where each unique first number has EXACTLY one second number. Or they could say that it is a way to match up to sets so that each member of the first set (domain) is connected to exactly ONE member of the second set (range). For the purposes of Physics, we restrain the sets to be the REAL NUMBERS and the connection rule is ALWAYS an Algebraic Statement (well at least in most of physics – there are exceptions in the very esoteric stuff, the really cool stuff).

Thus y = f(x) means put the number 'x' into the algebraic rule called 'f' and spit out its one and only value called 'y'. Above in  $f(x) = 3x^2 + 4x^3$ , we compute two separate terms (independently) and then sum the results. In the case above we could have factored  $x^2$  first two give  $f(x) = (3 + 4x)x^2$  but why make it messy by turning a simple sum into a multiplication!!

When you have a sum of two unknown functions one MUST determine each separately and then sum.

Thus if f(x) = g(x) + h(x) one must determine g(x) and h(x) separately and then sum their results.

In general we have,

$$\frac{f(x+\Delta x) - f(x)}{(x+\Delta x) - x} = \frac{\left[g(x+\Delta x) + h(x+\Delta x)\right] - \left[g(x) + h(x)\right]}{\Delta x}$$

or rearranging - invoking Rule 1 from page 2, we get

$$\frac{\left[g(x+\Delta x)+h(x+\Delta x)\right]-\left[g(x)+h(x)\right]}{\Delta x} = \frac{\left[g(x+\Delta x)-g(x)\right]+\left[h(x+\Delta x)-h(x)\right]}{\Delta x}$$

or rearranging further, we get

$$\frac{\left[g(x+\Delta x)-g(x)\right]+\left[h(x+\Delta x)-h(x)\right]}{\Delta x} = \frac{\left[g(x+\Delta x)-g(x)\right]}{\Delta x} + \frac{\left[h(x+\Delta x)-h(x)\right]}{\Delta x}$$

The two fractions on the right are just the slopes of function g(x) and h(x) added together.

Thus if a function is the sum of two functions then its slope is just the sum of the two slopes.

In our example, from just above

$$f(x) = 3x^2 + 4x^3.$$

The slope is simply  $6x + 12x^2$ .

## **Pause for Some Notation Notations!**

Now I am going to get awful tired of constantly saying "the slope of f(x) is" so let's create some notation that means the same thing.

If we have the function notation y = f(x).

Then at  $(x+\Delta x)$ ,  $(y+\Delta y) = f(x+\Delta x)$ 

Thus the slope is  $\frac{(y + \Delta y) - y}{(x + \Delta x) - x} = \frac{\Delta y}{\Delta x} = \frac{f(x + \Delta x) - f(x)}{\Delta x}$ 

Of course we are asking what happens to these ratios when  $\Delta x$  approaches zero.

The astute should notice that when  $\Delta x$  approaches zero, so does  $\Delta y$  and we end up with the famous 0/0 conundrum.

The sneaky thing that happens is that both top and bottom do go to zero together but the ratio keeps staying the same as they both approach zero.

Now we express this "approaching zero" constant ratio as simply the slope of the tangent line.

We then technically write that the slope is

$$\frac{dy}{dx} = (Limit \quad \Delta x \rightarrow \quad 0) \frac{\Delta y}{\Delta x} = slope$$

We also denote the slope of y = f(x) as f'(x) and is spoken as "f prime of x" Thus we have for the slope of y = f(x) the notation

$$\frac{dy}{dx} = f'(x)$$

We have one last little bit of jargon to deal with. The act of doing the slope is called "differentiation" and the result of differentiation is called the "derivative".

## The act of finding the slope of a line tangent to a curve is called differentiation. The result, which is the slope of the tangent line, is called the derivative.

If one wants to find a derivative, then one differentiates a function according to the prescribed rules.

Repeating the examples from above using the new notation:

$$y = f(x) = 2.4x^{4.5}$$
  

$$dy/dx = f'(x) = 4.5(2.4)x^{3.5} = 10.8x^{3.5}$$
  

$$y = f(x) = -4.2x^{0.5}$$
  

$$dy/dx = f'(x) = (0.5)(-4.2)x^{-0.5} = -2.1 x^{-0.5}$$
  

$$y = f(x) = 11.34x^{-3.4}$$
  

$$dy/dx = f'(x) = (-3.4)(11.34)x^{-4.4} = -38.556x^{-4.4}$$

What is important is that all we are doing is finding the slopes of tangent lines to curves.

## **End of Notation Notations**

#### Sum or Difference Rule:

What happens if we have a function which is the sum or difference of two functions?

$$y = f(x) = g(x) \pm h(x)$$

Doing the differentiation we get

 $\Lambda x$ 

$$\frac{f(x+\Delta x)\pm f(x)}{(x+\Delta x)-x} = \frac{\left[g(x+\Delta x)\pm h(x+\Delta x)\right] - \left[g(x)\pm h(x)\right]}{\Delta x} = \frac{\left[g(x+\Delta x)-g(x)\right]\pm \left[h(x+\Delta x)-h(x)\right]}{\Delta x}$$
$$\frac{\left[g(x+\Delta x)-g(x)\right]\pm \left[h(x+\Delta x)-h(x)\right]}{\left[h(x+\Delta x)-h(x)\right]} = \frac{\left[g(x+\Delta x)-g(x)\right]}{\pm \left[h(x+\Delta x)-h(x)\right]}$$

 $\Lambda x$ 

Note that the last two terms are simply the derivatives of g(x) and h(x).

Thus the derivative of the sum or difference of two functions is simply the sum or difference of the derivatives!

 $\Delta x$ 

#### THEREFORE WE HAVE THE FOLLOWING:

If y = f(x) = h(x) + g(x), then dy/dx = f'(x) = h'(x) + g'(x)

If 
$$y = f(x) = h(x) - g(x)$$
, then  $dy/dx = f'(x) = h'(x) - g'(x)$  (5 and 6)

Warning: the above rule does not work for products, quotients and compositions. We will now grind our way through each type of function manipulation.

#### **Product Rule:**

Suppose we have the function

$$y = f(x) = g(x)h(x)$$

Just in case you think these functions don't exist consider a rail coal car that is both having its speed and mass change as a function of time. The momentum p = mv, but both m and v are functions of t so the correct equation for momentum is

p = m(t) v(t)

which is the product of two functions. In fact the derivative of momentum is the technical definition of force.

So, that being said, how do we find the slope (derivative) of a product of two functions?

$$\frac{dy}{dx} = f'(x) = \frac{g(x + \Delta x)h(x + \Delta x) - g(x)h(x)}{\Delta x}$$

Well, there it is, but what to do with it? I will invoke RULE 2 from page 2 simply add zero to it in the following strange manner.

$$\frac{dy}{dx} = f'(x) = \frac{g(x + \Delta x)h(x + \Delta x) - g(x)h(x)}{\Delta x} = \frac{g(x + \Delta x)h(x + \Delta x) - g(x)h(x) + g(x + \Delta x)h(x) - g(x + \Delta x)h(x)}{\Delta x}$$

As strange as that seems it is logically legal since adding zero does not change the number (expression) on the right side of the equality thus the equality is still true. The last two terms are the same number except one is positive and the other is negative.

Now, rearranging the mess above we have

$$\frac{dy}{dx} = f'(x) = \frac{g(x + \Delta x)h(x + \Delta x) - g(x)h(x) + g(x + \Delta x)h(x) - g(x + \Delta x)h(x)}{\Delta x} = \frac{g(x + \Delta x)h(x + \Delta x) - g(x + \Delta x)h(x) + g(x + \Delta x)h(x) - g(x)h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)] + [g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)] + [g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x + \Delta x) - h(x)]}{\Delta x} + \frac{[g(x + \Delta x) - g(x)]h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x) + g'(x)h(x)]}{\Delta x} = \frac{g(x + \Delta x)[h(x) + g'(x)h(x)}{\Delta x} = \frac{g(x + \Delta x)[h(x) + g'(x)h(x)]}{\Delta x} = \frac{g(x + \Delta x)[h(x) + g'(x)h(x)}{\Delta x$$

Thus the derivative of y = f(x) = g(x)h(x) is

$$dy/dx = f'(x) = g(x)h'(x) + g'(x)h(x)$$
(7)

As a silly example consider the function with  $g(x) = 3x^2$  and  $h(x) = 4x^3$ 

$$y = g(x)h(x) = (3x^2)(4x^3) = 12x^5$$

This is a silly example since one can just multiply the two functions and then do the derivative.

If  $y = 12x^5$  then  $dy/dx = 60x^4$  from what we have already learned.

Now using the new rule we get

$$dy/dx = g(x)h'(x) + g'(x)h(x) = (3x^2)(12x^2) + (6x)(4x^3) = (36x^4) + (24x^4) = 60x^4$$

which is the same.

#### Warning: DO NOT MULTIPLY THE DERIVATIVES.

If you do multiply the derivatives in our example just above then you would erroneously get  $dy/dx = (6x^{1})(12x^{2}) = 72x^{3}$  THIS IS OBVIOUSLY WRONG – SO DON'T DO IT.

The Rule for differentiating functions multiplied together is

The FIRST times the derivative of the SECOND plus the derivative of the FIRST times the SECOND.

#### **Quotient Rule:**

What happens when you have one function divided by another?

y = f(x) = g(x)/h(x)

$$\frac{dy}{dx} = f'(x) = \frac{\frac{g(x + \Delta x)}{h(x + \Delta x)} - \frac{g(x)}{h(x)}}{\Delta x}$$

Now, to add (or subtract) fractions, one needs a common denominator. But, this common denominator is in the numerator of the larger fraction. Thus I will call this number the "common denumerator" – to coin a phrase.

$$\frac{dy}{dx} = f'(x) = \frac{\frac{g(x+\Delta x)}{h(x+\Delta x)} - \frac{g(x)}{h(x)}}{\Delta x} = \frac{\frac{g(x+\Delta x)h(x) - g(x)h(x+\Delta x)}{h(x+\Delta x)h(x)}}{\Delta x} = \frac{\frac{g(x+\Delta x)h(x) - g(x)h(x+\Delta x)}{\Delta x}}{\Delta x h(x+\Delta x)h(x)}$$
$$= \frac{1}{h(x+\Delta x)h(x)} * \frac{g(x+\Delta x)h(x) - g(x)h(x+\Delta x)}{\Delta x}$$

Now, I will do the magic add ZERO again. If you have to ask why I chose this particular ZERO then you have the makings of a mathematician. The answer is: After months (years) of trial an error Newton (Leibnitz?) found what works!!

$$\frac{dy}{dx} = f'(x) = \frac{1}{h(x + \Delta x)h(x)} * \frac{g(x + \Delta x)h(x) - g(x)h(x + \Delta x)}{\Delta x}$$
$$= \frac{1}{h(x + \Delta x)h(x)} * \frac{g(x + \Delta x)h(x) - g(x)h(x + \Delta x) + g(x)h(x) - g(x)h(x)}{\Delta x}$$
$$= \frac{1}{h(x + \Delta x)h(x)} * \frac{g(x + \Delta x)h(x) - g(x)h(x) - g(x)h(x + \Delta x) + g(x)h(x)}{\Delta x}$$
$$= \frac{1}{h(x + \Delta x)h(x)} * \frac{h(x)[g(x + \Delta x) - g(x)] - g(x)[h(x + \Delta x) - h(x)]}{\Delta x}$$

Please note the factorization in the last line. Read it carefully.

$$\frac{dy}{dx} = f'(x) = \frac{1}{h(x + \Delta x)h(x)} * \frac{h(x)[g(x + \Delta x) - g(x)] - g(x)[h(x + \Delta x) - h(x)]}{\Delta x}$$
$$= \frac{1}{h(x + \Delta x)h(x)} * \left[\frac{h(x)[g(x + \Delta x) - g(x)]}{\Delta x} - \frac{g(x)[h(x + \Delta x) - h(x)]}{\Delta x}\right]$$
$$= \frac{1}{h(x)h(x)} * [h(x)g'(x) - h'(x)g(x)] = \frac{h(x)g'(x) - h'(x)g(x)}{h(x)h(x)}$$

What this says is that the derivative of a ratio of two functions is:

The BOTTOM times the derivative of the TOP minus the derivative of the BOTTOM times the TOP ALL divided by the BOTTOM squared.

This a cute way of memorizing this technique:

Suppose you write f(x) = hi/ho (High over Hoe)

Then the derivative is Ho dHi – Hi dHo Over HoHo

Nice for a Christmas joke!

And now last but not the least – the most important of all!

#### **Chain Rule:**

Suppose you have a function of a function. In other words, compute a function then use the result of that computation to compute a second function. It sounds uncommon but it is very common. Here are some examples:

y = sin(2x). The 2x must be computed first then the sin computed.

 $y = (x^2+1)^3$ . Normally, one would compute the  $x^2+1$  first then cube the result though it could be expanded.

Now, suppose we have the following:

y = f(x) = g(h(x)) which simply means compute h(x) then use the result to compute the 'g' function.

What is the derivative of f(x)?

$$\frac{dy}{dx} = f'(x) = \frac{g(h(x + \Delta x)) - g(h(x))}{\Delta x}$$

Now, what does one do with this. Well the trick is to use RULE 3 from page 2 and multiply by ONE.

$$\frac{dy}{dx} = f'(x) = \frac{g(h(x + \Delta x)) - g(h(x))}{\Delta x} * \frac{h(x + \Delta x) - h(x)}{h(x + \Delta x) - h(x)}$$
$$= \frac{g(h(x + \Delta x)) - g(h(x))}{h(x + \Delta x) - h(x)} * \frac{h(x + \Delta x) - h(x)}{\Delta x}$$
$$= \frac{g(h(x + \Delta x)) - g(h(x))}{h(x + \Delta x) - h(x)} * h'(x)$$

Now we have to get sneaky and name

z = h(x) which also implies that  $z+\Delta z = h(x+\Delta x)$  giving us

$$\frac{dy}{dx} = f'(x) = \frac{g(h(x + \Delta x)) - g(h(x))}{h(x + \Delta x) - h(x)} * h'(x)$$
$$= \frac{g(z + \Delta z) - g(z)}{(z + \Delta z) - z} * h'(x)$$
$$= \frac{g(z + \Delta z) - g(z)}{\Delta z} * h'(x)$$
$$= g'(z) * h'(x)$$
$$= g'(h(x)) * h'(x)$$

What the gobble-de-gook above means is that one takes the derivative of the 'outer' function and just write the inner function then multiplies by the derivative of the inner function.

This takes some examples:

First let's use the second example from the start of the Chain Rule which was

$$y = f(x) = g(h(x)) = (x^2+1)^3$$

This is a combination of

$$h(x) = x^2 + 1$$

and

$$g(x) = x^3$$

$$g'(x) = 3x^2$$
  
or  $g'(h(x)) = 3(h(x))^2 = 3(x^2+1)^2$ 

and

h'(x) = 2x + 0 = 2x

Therefore,

$$dy/dx = f'(x) = g'(h(x))h'(x) = 3(x^2+1)^2(2x) = 6x(x^2+1)^2 = 6x(x^4+2x^2+1) = 6x^5+12x^3+6x^2+1$$

Now let's show that this is right by doing the derivative another way. The original function was

 $y = f(x) = (x^2+1)^3 = x^6+3x^4+3x^2+1$  when expanded out.

 $dy/dx = f'(x) = 6x^5 + 12x^4 + 6x$  Both derivatives are the same.

#### Multiplying a function by a constant:

I have left this item to last simply because I forgot to do it earlier!

Suppose we have the function  $y = k^*f(x) = kf(x)$  where k=constant. What is its derivative?

$$y = k f(x)$$
, therefore  $y' = \frac{dy}{dx} = \frac{k(f(x + \Delta x) - kf(x))}{\Delta x} = k \left[\frac{f(x + \Delta x) - f(x)}{\Delta x}\right] = kf'(x)$ 

Well, that was easy. The derivative of a constant times a function is the constant times the derivative of the function.

Before you can use Calculus you will need to do LOTS of practice taking derivatives of many functions before you are ready to use Calculus as a tool in Physics and other areas.

#### Review of what we have learned so far (yes there is more to learn).

If  $y = kx^n$  then  $dy/dx = nkx^{n-1}$ . This is the ONLY function specific rule – so far.

If y = f(x) + g(x) then dy/dx = f'(x) + g'(x)

If y = f(x) - g(x) then dy/dx = f'(x) - g'(x)

If y = f(x)g(x) then dy/dx = f(x)g'(x) + f'(x)g(x)

If y = f(x)/g(x) then  $dy/dx = (g(x)f'(x) - f(x)g'(x))/(g(x))^2$ 

If y = f(g(x)) then dy/dx = f'(g(x))g'(x)

If y = kf(x) (k constant) then dy/dx = kf'(x)

Practice will make you perfect – EVENTUALLY!

Outside of polynomials, there are as many specialty (non-polynomial) functions as there are grains of sand in the universe. We will concern ourselves with a very useful (and small) subset of these functions. They are:

y = sin(x) y = cos(x)  $y = a^{x}$   $y = e^{x}$  y = ln(x) y = sin(x): $dy = sin(x + \Delta x) - sin(x)$ 

 $\frac{\mathrm{d}y}{\mathrm{d}x} = \frac{\sin(x + \Delta x) - \sin(x)}{\Delta x}$ 

Now what to do? The trick is to convert the left term in the numerator using a trig identity that we all know and remember with fondness. If you are not in that group that remembers such stuff, then get a math book out and look up trig identities.

I will use the infamous identity  $\sin(a \pm b) = \sin(a)\cos(b) \pm \cos(a)\sin(b)$ .

$$\frac{dy}{dx} = \frac{\sin(x + \Delta x) - \sin(x)}{\Delta x} = \frac{\sin(x)\cos(\Delta x) + \sin(\Delta x)\cos(x) - \sin(x)}{\Delta x}$$

Now, slightly rearrange and then do a bit of factoring.

$$\frac{\mathrm{d}y}{\mathrm{d}x} = \frac{\sin(x)\cos(\Delta x) + \sin(\Delta x)\cos(x) - \sin(x)}{\Delta x} = \frac{\sin(x)\left[\cos(\Delta x) - 1\right] + \sin(\Delta x)\cos(x)}{\Delta x}$$
$$= \frac{\sin(x)\left[\cos(\Delta x) - 1\right]}{\Delta x} + \frac{\sin(\Delta x)\cos(x)}{\Delta x} = \sin(x)*\frac{\left[\cos(\Delta x) - 1\right]}{\Delta x} + \cos(x)*\frac{\sin(\Delta x)}{\Delta x}$$

Now it is time to bypass the Limit method you will learn (or have already seen) in Calculus and just do some arithmetic. (Note to student: this is a live Excel Chart – just double click on it if you are reading this file in MS  $Word^{\circ}$ .)

The first column starts out with common angles in degrees until 1° and then just starts halving the previous angle ad infinitum.

The second column is the degree converted into radians. It probably is worth noting (maybe even making a big deal) that a radian is NOT a unit. It is simply a fancy way of saying ONE – the ratio of the arc length to the radius thus its construction units cancel. In fact we will see examples later (particularly in Simple Harmonic Motion and Rotations) where the word radian is purposely ignored and in fact deleted. By the way 1 radian =  $180^{\circ}/\pi = about 57.296^{\circ}$ .

All the other columns do Trig with the radian value since Excel does Trig in radians.

The fifth column is the ratio 
$$\frac{\cos(\Delta x) - 1}{\Delta x}$$
 which approaches ZERO as  $\Delta x \rightarrow 0$ .

The seventh column is the ratio  $\frac{\sin(\Delta x)}{\Delta x}$  which approaches ONE as  $\Delta x \rightarrow 0$ .

#### Small digression before returning to Calculus:

This last fact above is very useful when we need to simplify a hard to compute problem. Having a ratio approach ONE simply implies that the numerator and denominator become the SAME number as the denominator approaches zero. Thus if one has a process that uses the sine of small angles one can often just use the angle itself instead of the sine of the angle. Look back at the table. At  $30^{\circ}$ , the  $sin(30^{\circ})$  and  $30^{\circ}$  in radians are within 5% of each other. At  $15^{\circ}$  the two numbers are within 1.1%. At  $5^{\circ}$ , the numbers are within 0.1%. This means that if you are measuring with errors of 5% you can simply use the angle (in radians) instead of the sine(angle) up to  $30^{\circ}$ . If you are less than 1% you can switch below  $5^{\circ}$ .

We will use this "Small Angle Conversion" when we study Simple Harmonic Motion and when we look at Interference (assuming we have the time).

#### End small digression, on with Calculus.

The ratios above imply the following:

$$\frac{\mathrm{dy}}{\mathrm{dx}} = \frac{\sin(x)\cos(\Delta x) + \sin(\Delta x)\cos(x) - \sin(x)}{\Delta x} = \frac{\sin(x)\left[\cos(\Delta x) - 1\right] + \sin(\Delta x)\cos(x)}{\Delta x}$$
$$= \frac{\sin(x)\left[\cos(\Delta x) - 1\right]}{\Delta x} + \frac{\sin(\Delta x)\cos(x)}{\Delta x} = \sin(x)*\frac{\left[\cos(\Delta x) - 1\right]}{\Delta x} + \cos(x)*\frac{\sin(\Delta x)}{\Delta x}$$
$$= \sin(x)*ZERO + \cos(x)*ONE = \cos(x)$$

Thus the derivative of sin(x) is cos(x). Now that is a nice and easy fact!

### y = cos(x):

Now let's find the derivative of cos(x).

$$\frac{dy}{dx} = \frac{\cos(x + \Delta x) - \cos(x)}{\Delta x} = \frac{\cos(x)\cos(\Delta x) - \sin(x)\sin(\Delta x) - \cos(x)}{\Delta x} = \frac{\cos(x)\left[\cos(\Delta x) - 1\right] - \sin(x)\sin(\Delta x)}{\Delta x}$$
$$= \cos(x)*\frac{\left[\cos(\Delta x) - 1\right]}{\Delta x} - \sin(x)*\frac{\sin(\Delta x)}{\Delta x}$$

We used the Trig Identity  $\cos(a \pm b) = \cos(a)\cos(b) \mp \sin(a)\sin(b)$ 

Those two ratios should look very familiar from above so let's just use them.

$$\frac{\mathrm{d}y}{\mathrm{d}x} = \cos(x) * \frac{\left[\cos(\Delta x) - 1\right]}{\Delta x} - \sin(x) * \frac{\sin(\Delta x)}{\Delta x} = \cos(x) * ZERO - \sin(x) * ONE = -\sin(x)$$

Thus, the derivative of cos(x) is -sin(x).

Note that the slope numbers of the sine curve are the same numbers as the cosine curve which implies that

If  $y = \sin(x)$  then  $dy/dx = y' = \cos(x)$ .

Note also that the slope numbers of cosine are the negative of the sine numbers implying that

If y = cos(x) then dy/dy = y' = -sin(x).

Without further ado, let's find the derivative of the tangent function. We don't really need to know it for AP Physics but it is cute since you now have ALL the tools you need to do it.

$$y = \tan(x) = \frac{\sin(x)}{\cos(x)}, \text{ therefore the division rule}$$

$$y' = \frac{dy}{dx} = \frac{bottom * top \ slope \ - \ top * bottom \ slope}{bottom^2} = \frac{\cos(x)\cos(x) - \sin(x)(-\sin(x))}{[\cos(x)]^2}$$

$$= \frac{[\cos(x)]^2 + [\sin(x)]^2}{[\cos(x)]^2} = \frac{1}{[\cos(x)]^2} = [\sec(x)]^2$$

This is just an example of how we can handle what look like hard problems by breaking them down into known chunks and applying the rules.

Now for your first major REAL PHYISCS STUFF using Calculus!

Suppose we have an object moving in a circle of radius R with a period T.

The speed of the object is simply the circumference divided by the period, thus we have

$$v = \frac{2\pi R}{T}$$
. From last year, we also know the centripetal acceleration to be  $a_c = \frac{v^2}{R} = \frac{\left[\frac{2\pi R}{T}\right]^2}{R} = \frac{4\pi^2 R}{T^2}$ .

We arrived at  $a_c$  by some slight chicanery last year that was not really truly valid. We will now do it via Calculus.

(NOTE to student: I am making the assumption that you have practiced doing derivatives until you are sick of them!)

If the object is moving around the circle with a velocity  $2\pi R/T$  then where is it at any intermediate time 't'?

Letting x = vt (Basic physics) we get  $Z = \frac{2\pi R}{T}t$  where Z is length along the circumference. The central angle

shown above as ' $\Theta$ ' is then simply (in radians)  $\Theta = \frac{Z}{R} = \frac{\frac{2\pi R}{T}t}{R} = \frac{2\pi}{T}t$ .

At time t, the object has moved from (R,0) to (x,y). Now we actually know (x,y) by doing trigonometry!!

$$\frac{x}{R} = \cos(\Theta) = \cos(\frac{2\pi}{T}t)$$
or
$$x = R\cos(\frac{2\pi}{T}t)$$

Repeating for y we get

$$\frac{y}{R} = \sin(\Theta) = \sin(\frac{2\pi}{T}t)$$
or
$$y = R\sin(\frac{2\pi}{T}t)$$

Now, both x and y are functions of 't'. We can now actually compute how fast the object is traveling along each axis by differentiating each function (Slope of position is velocity.) Note the use of the Chain Rule below!!

$$x = R\cos(\frac{2\pi}{T}t)$$

or

$$v_x = \frac{dx}{dt} = R \left[ -\sin(\frac{2\pi}{T}t) \right] \frac{2\pi}{T} = -\frac{2\pi R}{T} \sin(\frac{2\pi}{T}t)$$

It may be hard to see but I have invoked THREE (3) of the differentiation rules:

- 1. The last rule Constant times a function
- 2. The derivative of the Sine function
- 3. The Chain Rule

Repeating for y we get

$$y = R\sin(\frac{2\pi}{T}t)$$

or

$$v_{y} = \frac{dy}{dt} = R \left[ \cos(\frac{2\pi}{T}t) \right] \frac{2\pi}{T} = \frac{2\pi R}{T} \cos(\frac{2\pi}{T}t)$$

Note that  $V_x$  and  $V_y$  are both components of the actual 'slant' or tangential velocity as the object moves along the circle. This means we can use the Pythagorean Theorem to calculate the actual velocity.

$$V = \sqrt{V_x^2 + V_y^2} = \sqrt{\left[-\frac{2\pi R}{T}\sin(\frac{2\pi}{T}t)\right]^2 + \left[\frac{2\pi R}{T}\cos(\frac{2\pi}{T}t)\right]^2}$$
$$= \sqrt{\left[\frac{2\pi R}{T}\right]^2 \left(\sin^2(\frac{2\pi}{T}t) + \cos^2(\frac{2\pi}{T}t)\right)} = \sqrt{\left[\frac{2\pi R}{T}\right]^2 (1)} = \frac{2\pi R}{T} = \frac{Circumference}{Period}$$

Thus Calculus has solved a problem we already knew the answer to with far more sweat!!

But, wait, there is more. We have the x and y velocity equations. We can compute the accelerations along each axis doing exactly the same thing.

$$v_{x}'(t) = a_{x} = \frac{dv_{x}}{dt} = -\frac{2\pi R}{T}\cos(\frac{2\pi}{T}t)\frac{2\pi}{T} = -\frac{4\pi^{2}R}{T^{2}}\cos(\frac{2\pi}{T}t)$$

and

$$v_{y}'(t) = a_{y} = \frac{dv_{y}}{dt} = \frac{2\pi R}{T} \left[ -\sin(\frac{2\pi}{T}t) \right] \frac{2\pi}{T} = -\frac{4\pi^{2}R}{T^{2}} \sin(\frac{2\pi}{T}t)$$

Now using the Greek Guy again we find the net (Centripetal Acceleration) as follows:

$$\begin{aligned} a_c &= \sqrt{{a_x}^2 + {a_y}^2} = \sqrt{\left[ -\frac{{4{\pi ^2}R}}{{{T^2}}}\cos (\frac{{2\pi }}{T}t) \right]^2} + \left[ -\frac{{4{\pi ^2}R}}{{{T^2}}}\sin (\frac{{2\pi }}{T}t) \right]^2} = \sqrt{\left[ -\frac{{4{\pi ^2}R}}{{{T^2}}} \right]^2} \left( {\sin ^2}(\frac{{2\pi }}{T}t) + \cos ^2(\frac{{2\pi }}{T}t) \right) \\ &= \sqrt{\left[ -\frac{{4{\pi ^2}R}}{{{T^2}}} \right]^2}(1) = \frac{{4{\pi ^2}R}}{{{T^2}}} \end{aligned}$$

Note that this is the same equation as way above. The only difference is that we derived it from basic physics and Calculus without the usual 'hand waving' we used in Honors Physics.

Just one of MANY examples you will see during the year of the power of Calculus. Get Used to it!!

Now we have to interlocking functions that appear from time to time in this course. They are the exponential functions given by:

 $y = a^{x}$ and  $y = e^{x}$ 

And their INVERSE functions given by:

$$y = \log_a(x)$$
  
and  
$$y = \ln(x)$$

I will derive the derivatives by using the same computer approximation as I did for sine and cosine.

I will do  $y = a^x$  first and then extend it to  $y = 10^x$  and  $y = e^x$ .

 $y=a^x$ 

 $y = a^x$ 

Therefore

 $y' = \frac{dy}{dx} = \frac{a^{x + \Delta x} - a^x}{\Delta x} = \frac{a^x a^{\Delta x} - a^x}{\Delta x} = a^x \frac{a^{\Delta x} - 1}{\Delta x}$ 

Now, just what is that strange function  $\frac{a^{\Delta x} - 1}{\Delta x}$ ?

Using Excel once again let's play with it (this is also a live spreadsheet in  $Word^{\mathbb{C}}$ .)

$a=$ 2 $a^{\Delta x}$

			l n(10) =	2.3025851			Ln(143.296)=	4,9649124

As you can see, the strange little fraction  $\frac{a^{\Delta x} - 1}{\Delta x}$  approaches Ln(a) as  $\Delta x \rightarrow 0$ . We suggest you open the spreadsheet and play with the values of 'a' to see what happens. Thus the derivative of y=a<sup>x</sup> is simply

$$y = a^{x}$$
  
thus  
$$y' = \frac{dy}{dx} = a^{x}Ln(a)$$

This works for any POSITIVE 'a'.

As you might guess, the above table(s) are NOT proofs, they are demonstrations. I leave the hard stuff to the Calculus teachers

For Base 10 we have

$$y = 10^{x}$$
Thus
$$\frac{dy}{dx} = 10^{x} Ln(10) = 2.3025851 * 10^{x}$$
Also, for  $y = e^{x}$ 

$$\frac{dy}{dx} = e^{x} Ln(e) = 1 * e^{x} = e^{x}$$
Recall that  $\ln(e) = 1$ 

This little derivative fully explains why  $y=e^x$  is so common in upper math and science courses. The derivative is the same as the original function. Sure doesn't take much work to do a derivative.

### y=ln(x)

Now, last but not least we will need to know the derivative of y=Ln(x). We actually will never use  $y=Log_a(x)$  in this course.

# Given y = Ln(x) $y' = \frac{dy}{dx} = \frac{Ln(x + \Delta x) - Ln(x)}{\Delta x}$

Now, what can we do with that little ditty. Simple, just remember your logarithm manipulation rules!

Given  

$$y = Ln(x)$$

$$y' = \frac{dy}{dx} = \frac{Ln(x + \Delta x) - Ln(x)}{\Delta x} = \frac{1}{\Delta x} Ln \left[ \frac{x + \Delta x}{x} \right] = \frac{1}{\Delta x} Ln \left[ 1 + \frac{\Delta x}{x} \right]$$

$$= \frac{x}{x} \frac{1}{\Delta x} Ln \left[ 1 + \frac{\Delta x}{x} \right] = \frac{1}{x} \frac{x}{\Delta x} Ln \left[ 1 + \frac{\Delta x}{x} \right] = \frac{1}{x} Ln \left[ 1 + \frac{\Delta x}{x} \right]^{\frac{x}{\Delta x}}$$
Now, what does one do with the little ditty  $\left[ 1 + \frac{\Delta x}{x} \right]^{\frac{x}{\Delta x}}$ ?

Well, once again we go to Excel and just let it play with the numbers and see what happens.

BTW: $Mess = \left[1 + \frac{\Delta x}{x}\right]^{\frac{x}{\Delta x}}$										
	x= 1				x=	x= 100				
	Δx	Δx/x	Mess		Δx	∆x/x	Mess

	0.0000010	0.0000010000	2.7182805		0.0000010	0.0000001000	2.7182818			
	0.0000001	0.0000001000	2.7182817		0.0000001	0.0000000100	2.7182821			
	0.0000000	0.000000100	2.7182818		0.0000000	0.0000000010	2.7182821			
	0.0000000	0.000000010	2.7182821		0.0000000	0.0000000001	2.7182821			
	x=	10			x=	0.1				
	Δx	Δx/x	Mess		Δx	∆x/x	Mess			
	1.0000000	0.100000000	2.5937425		1.0000000	10.0000000000	1.2709816			
	0.1000000	0.010000000	2.7048138		0.1000000	1.0000000000	2.0000000			
	0.0100000	0.001000000	2.7169239		0.0100000	0.1000000000	2.5937425			
	0.0010000	0.0001000000	2.7181459		0.0010000	0.0100000000	2.7048138			
	0.0001000	0.0000100000	2.7182682		0.0001000	0.0010000000	2.7169239			
	0.0000100	0.0000010000	2.7182805		0.0000100	0.0001000000	2.7181459			
	0.0000010	0.000001000	2.7182817		0.0000010	0.00001000000	2.7182682			
	0.0000001	0.000000100	2.7182818		0.0000001	0.00000100000	2.7182805			
	0.0000000	0.000000010	2.7182821		0.0000000	0.0000010000	2.7182817			
	0.0000000	0.000000001	2.7182821		0.0000000	0.0000001000	2.7182818			

Note that in every case above, the 'ditty'  $\left[1 + \frac{\Delta x}{x}\right]^{\frac{x}{\Delta x}}$  regardless of the value of x, always becomes 2.71823... which is better known as 'e'.

Thus we have

Given  

$$y = Ln(x)$$

$$y' = \frac{dy}{dx} = \frac{Ln(x + \Delta x) - Ln(x)}{\Delta x} = \frac{1}{\Delta x} Ln \left[ \frac{x + \Delta x}{x} \right] = \frac{1}{\Delta x} Ln \left[ 1 + \frac{\Delta x}{x} \right]$$

$$= \frac{x}{x} \frac{1}{\Delta x} Ln \left[ 1 + \frac{\Delta x}{x} \right] = \frac{1}{x} \frac{x}{\Delta x} Ln \left[ 1 + \frac{\Delta x}{x} \right] = \frac{1}{x} Ln \left[ 1 + \frac{\Delta x}{x} \right]^{\frac{x}{\Delta x}} = \frac{1}{x} Ln(e) = \frac{1}{x}$$

Thus the derivative of  $y=\ln(x)$  is simply y'=dy/dx = 1/x. Again, this is a very simple result.

This material represents all of the derivative information you need for the AP-C Physics course.

#### However, you just knew there was a however! It is only half of the needed knowledge.

# **Integral Calculus:**

From the first lab last year in Honors Physics and extended during the year there is a strong connection between finding slopes of curves and finding the area under the curve.

Without doing the entire fancy math done in a REAL Calculus class let's just list what we learned last year.

- 1. The slope of a position curve is velocity.
- 2. The area under a velocity curve is change in position.
- 3. The slope of a velocity graph is the acceleration.
- 4. The area under an acceleration graph is the change in velocity.

Suppose we have the equation

V = dx/dt which just says that the velocity is the slope of position graph.

We can rewrite the equation is dx = Vdt

In the graph, the gray shaded area is approximately a trapezoid with an average height of  $\overline{V}$  better known as the average velocity. If the interval is very small the Average Velocity will simply be the average of the end points. The area, which we know from last year, will tell us how far we traveled during the interval dt. The area is simply  $\overline{V}dt$  which is also dx from above. Thus the TOTAL change in 'x' is simply the sum of the little changes in each little area of width dt.

But, the change in x can also be computed by simply subtracting the initial position from the final position.

What we have is the sum of all the Vdt's from  $t_i$  to  $t_f$  will give us the TOTAL  $dx = x_f x_i$ .

Now, suppose we have more than just data but we have an actual function that represents the velocity curve.

Suppose v = f(t).

We already know that this function f(t) is a slope of a position function (last year). Also, we know how to find slopes. Thus we need to UNSLOPE v=f(t). We need to find a function that has as its slope, f(t).

Some examples:

Suppose v = 2t.

What function when differentiated gives v=2t? Simply it is  $x=t^2$ . Just differentiate the second equation.

Thus we know that  $x = t^2$  will get the job done.

If  $x = t^2$ , the dx/dt = v = 2t. However, there are actually infinitely many such equations.

Suppose  $x = t^2 + 3$ , then v = dx/dt = 2t, also. In fact the 3 could be any constant and it would still work. What we do is simply add a C (constant) to the UNSLOPE to get the general equation.

So, if v=2t then  $x = t^2 + C$ .

Now, going back up, we know that the total area under the curve between  $t_i$  and  $t_f$  is the total dx for the curve but we also know that  $dx = x_f - x_i$ .

This allows us to determine the area under the curve by simply computing  $x_f$  and  $x_i$  and then subtracting them.

In our case above,  $x = t^2 + C$  which means that  $x_f = t_f^2 + C$  and  $x_i = t_i^2 + C$ .

Total dx =  $x_f - x_i = (t_f^2 + C) - (t_i^2 + C) = t_f^2 - t_i^2$ .

What we have done is simply find the ANTDERIVATIVE of the function and plug in the endpoints and subtract.

But we are also adding up infinitely many minute area slices under the curve which is called integration.

The INTEGRAL is a fancy word for anti-derivative which is a fancy word for UNSLOPE which is an ugly word meaning undo the derivative you did to make the function we are now trying to undo (READ THAT SEVERAL TIMES – FAST).

The constant 'C' is called the Constant of Integration and depends on knowing the values of the variables in the Integral at some point.

Thus, to find the area under a curve between two points on the x-axis, find the curves integral, plug in the two specific endpoints and subtract. You are done.

For the Calculus freaks, this is called the Fundamental Theorem of Calculus

#### Some more examples:

1. Find the area under  $y=3x^2$  between x=1 and x=5.

The Integral (anti-derivative = unslope) is  $Y = x^3 + C$  where Y' = y. Computing Y(5) - Y(1) = (125+C) - (1+C) = 124

Voila, we are done.

2. If my velocity is given by  $v = 4t^3+t^2+2$ . How far to I travel between t=0 and t =2?

The integral is  $x = t^4 + (1/3)t^3 + 2t + C$ .

The area is  $x(2) - x(0) = (2^4 + (1/3)2^3 + 2(2) + C) - (0+0+0+C) = (16 + 8/3 + 4 + C) - (C) = 222/3$ 

3. What is the area under a sine curve from x=0 to  $x = \pi/2$ ?

Find the integral of y = sin(x). The slope of cos(x) = -sin(x) therefore the integral must be Y = -cos(x) + C.

Plug in the endpoints and  $Y = (-\cos(\pi/2) + C) - (-\cos(0) + C) = (-0 + C) - (-1 + C) = 1$ .

Thus the area under a half hump from 0 to  $\pi$ /s must be 1. Whoopee do!

4. Suppose a force is applied to a car which is a function of the cars position. How much work Must be done to move the car from x = 2 to x = 4 if the force function is F(x) = 300x. (Newtons)

This could easily be accomplished by a strong spring. In fact we did this last year during The Energy part of the course when we studied springs. The work done is simply the area under a Force as a function of Distance curve.

Since we need an area just do it again.

Integral of  $F(x) = 150x^2 + C$ . BTW: Do you remember the formula for spring energy =  $(1/2)kx^2$ ?

Plug in the endpoints and we get the area =  $(150(4)^2 + C) - (150(2)^2 + C) = 150(12) = 1800$  Joules.

5. Suppose we have the following information.  $V = 5t^2$  and x = 3 at t=2. What equation represents the objects acceleration and what equation represents the objects position?

The acceleration is simply the derivative of the velocity, thus a=dv/dt=10t and we are done.

The integral is  $x = (5/3)t^3 + C$ ; however, we know that x=3 when t=2. Using that information solve for C, we get  $3 = (5/3)2^3 + C$ , or C = 3-(5/3)8 = -10.33. The position equation is  $x = (5/3)t^3 - 10.33$ .

6. Suppose we cause a car to accelerate constantly at a, require that  $v=v_i$  and  $x = x_i$  at t=0. What will be

the cars velocity and position at some later time t?

The relationship between acceleration and velocity is the same as the relationship between velocity and position. Thus to find acceleration we simply integrate the acceleration.

Given that Acc = a, the integral MUST be v = at + C. But, at t=0  $v = v_i$ . Therefore,  $v_i = a(0) + C$  or  $C = v_i$ . Therefore  $v = at + v_i$ . This is the same equation we used all last year.

Now, to find position we just integrate velocity  $(v = at + v_i)$  which gives  $x = (1/2)at^2 + v_it + C$ . (Note: this 'C' is a different 'C'). Therefore  $x_i = (1/2)a(0)^2 + v_i(0) + C$  or  $C = x_i$ . The final function is  $x_f = (1/2)at^2 + v_it + x_i$ . This is the same as the equation from last year.

7. Demonstration that the anti-derivative is the same as the area under the curve. Suppose we have an object moving in such a way that its velocity is given by  $v = 2t^3 + 4t + 2$ . How far would it travel between t=1s and t=3 s?

Using Calculus, we simply find the integral (anti-derivative, unslope) and plug in the x-axis end points and subtract. Let's do it.  $x = (1/4)(2)t^4 + 2t^2 + 2t + C$ . Computing x(3) - x(1) we get,

$$dx = \left[ \left(\frac{1}{2}\right)(3^{4}) + 2(3^{2}) + 2(3) + C \right] - \left[ \left(\frac{1}{2}\right)(1^{4}) + 2(1^{2}) + 2(1) + C \right]$$
$$= \left[ \frac{1}{2}(81) + 2(9) + 6 + C \right] - \left[ \left(\frac{1}{2}\right)(1) + 2(1) + 2(1) + C \right] = \left[ 40.5 + 18 + 6 + C \right] - \left[ 0.5 + 4 + C \right] = 60$$

This is so darn simple (on the surface!)

Now, I am going to use a special mathematical method to find the actual areas by doing what we did last year in adding up a whole bunch of small trapezoids under the curve.

Suppose we have the function v = 3t. What is the change in position between t = 1 and t = 4?

Using the stuff you have just been shown, we just integrate our little function, plug in the end points and simply subtract.

x =  $(3/2)t^2$ +C. The change in x from t=1 to t=4 is simply dx =  $((3/2)4^2$ +C) -  $((3/2)1^2$ +C) or dx = (3/2)16-(3/2)1 = (3/2)15 = 45/2 = 22.5

Now lets actually compute the area by adding up little trapezoids (yee-ha)!

The graph above shows the velocity curve, v = 3t, and I have added some sample trapezoids along the length from t=1s to t=4s. Please assume there are 'n' such trapezoids in the gap from t=1s to t=4s.

If the gaps are all the same width, then each dt is (4-1)/n = 3/n wide. The average height of each trapezoid is approximately the height or the right edge of the trapezoid. (We could just as easily use the left edge or the average height.)

The right edge of trapezoid #1 ends at t = 1 + 1\*(3/n). Thus the height is simply v = 3(1 + 1\*(3/n)). The area of the trapezoid is height \* width = v\*dt = 3(1+1\*(3/n))\*3/n.

The right edge of trapezoid #2 ends at t=1 + 2\*(3/n). Thus the height is v = 3(1+2(3/n)). The area is 3(1+2(3/n))\*3/n.

The right edge of trapezoid #3 ends at t= 1 + 3\*(3/n). Thus the height is v = 3(1+3\*(3/n)). The area is 3(1+3\*(3/n))\*3/n.

. . . . . . .

The right edge of the n<sup>th</sup> trapezoid end at t=1+n(3/n) = 4 (dah!). The height is 3(1+n(3/n)). The area is 3(1+n(3/n))\*3/n.

Now the total area (approximated) is

 $AREA = 3(1+1*(3/n))*3/n + 3(1+2(3/n))*3/n + 3(1+3*(3/n))*3/n + \dots + 3(1+n(3/n))*3/n.$ 

Now, using RULE 1 from page 2, expand this expression.

$$AREA = 9/n + 1*27/n^2 + 9/n + 2*27/n^2 + 9/n + 3*27/n^2 + \dots + 9/n + n*27/n^2.$$

or

$$AREA = (9/n + 9/n + 9/n + \dots + 9/n) + (1*27/n^2 + 2*27/n^2 + 3*27/n^2 + \dots + n*27/n^2).$$

or

AREA = 9\*(
$$1/n + 1/n + 1/n + ... + 1/n$$
) + (27/n<sup>2</sup>)\*( $1 + 2 + 3 + ... + n$ ).

Since there are n rectangle, adding up the same number n times gives  $n^{*}$  (the number). In our case the The same number is (1/n) thus n(1/n) = 1 giving

AREA = 
$$9*(1) + (27/n^2)*(1 + 2 + 3 + ... + n)$$
.

Now is their a nifty formula (1 + 2 + 3 + ... + n)? Why of course!!

Suppose S = 1 + 2 + 3 + ... + nAlso S = n + n-1 + n-2 + ... + 1Sum 2S = (n+1) + (n+1) + (n+1) + .... + (n+1) = n(n+1).

Therefore  $S = (1/2)n^*(n+1)$ . Try it out!!

Thus

AREA =  $9*(1) + (27/n^2)*((1/2)n(n+1))$ 

or

 $AREA = 9 + (27/n^{2})(1/2)(n^{2} + n) = 9 + (13.5/n^{2})(n^{2} + n) = 9 + 13.5 + 13.5/n = 22.5 + 13.5/n.$ 

If we let  $n \rightarrow \infty$  then  $13.5/n \rightarrow 0$  and we have

AREA = 22.5, which is the same as back away, using Calculus.

This should convince you that we don't really want to calculate areas this way. However, it is actually rather common when the function to be integrated is to hard to integrate symbolically.

BTW: In this particular case we could have simply calculated the area since the ORIGINAL area is itself a simple trapezoid.

AREA = (Average Height)\*(Base) = (3+12)/2 \* 3 = (15/2)\*3 = 45/2 = 22.5.

What, you are seeing is that Calculus is ready made to make Physics easier (if and only if, one can use functional equations instead of discrete data points as we did last year). This means that there is going to a strong reliance on fitting functions to data in this class. Of course we also did it last year with linear

regression. We will continue with linear regression and add polynomial and log-log curve fits as the year progresses.

What you are seeing is simply the following statement. If a function represents a derivative then both the area under that derivative and the function which produced that derivative (the Integral) are obtained by essentially the same process.

What you are not seeing is the HARD fact that the act of Integration is far more difficult than the act of differentiation. Differentiation is taught in a week. Integration takes multiple courses and you have only begun.

As a famous comedian (well, famous to old people) used to say after his opening monologue,

"And away we go!!"

First test.

- 1. Who said it?
- 2. What famous skit was played on every show?
- 3. What part did he play in the script?
- 4. What physical act did he do after saying, "And away we go!"
